# UNI CANTEEN SERVER INSTALLATION AND CONFIGURATION

## 1. INSTALLATION

Creating and configuring a server is a must do task on the development of the information system. Having a server allows us to host data and hosting a domain for our website. There are so many options out there but in our case we have decided to use Ubuntu Server 22.04.

This operating system is quite popular due to its simplicity and accessibility, and is also available in several languages. One of the advantages of Ubuntu is that it is easy to understand and its software system gets along well with other systems, such as Windows.

First of all we have installed Ubuntu Server on a virtual machine using the IsardVDI tool. IsardVDI is a free virtualization tool under the AGPL3 license. The tool has been developed thinking about desktop virtualization in an educational center.

The first step is to use a template and add the Ubuntu Server ISO. We have specified to the virtual machine to start the boot from the cd and once the installation is completed we have changed it to initialize from the hard disk.

Besides this we have also added the network of our classroom that is the one called vlan72. This is important because we have some IP's available on that network, so the server must be on the network to apply for the right IP address.

ubuntu-22.04-live-server-amd64 iso x

Floppies

After specifying these parameters we have started the virtual machine to initialize the installation of the Ubuntu Server. As we said before when we start the virtual machine the boot will be made from the CD. This aspect will be temporary because once the installation is completed will be changed on the options of the virtual machine. The ISO that is added also can be removed once the installation is completed.

The first aspects of the installation are the language of the distribution of the keyword and the configuration of the version. In this case we have entered the Spanish version of the keyword and we have left the current version of Ubuntu Server; 22.04.

4

The next steps of the installation are the configuration of the structure of the disk and the specification of the accounts data. When specifying the structure of the disk you can create new partitions and configure taking into account the needs of the situation. In our case we have left the default configuration.

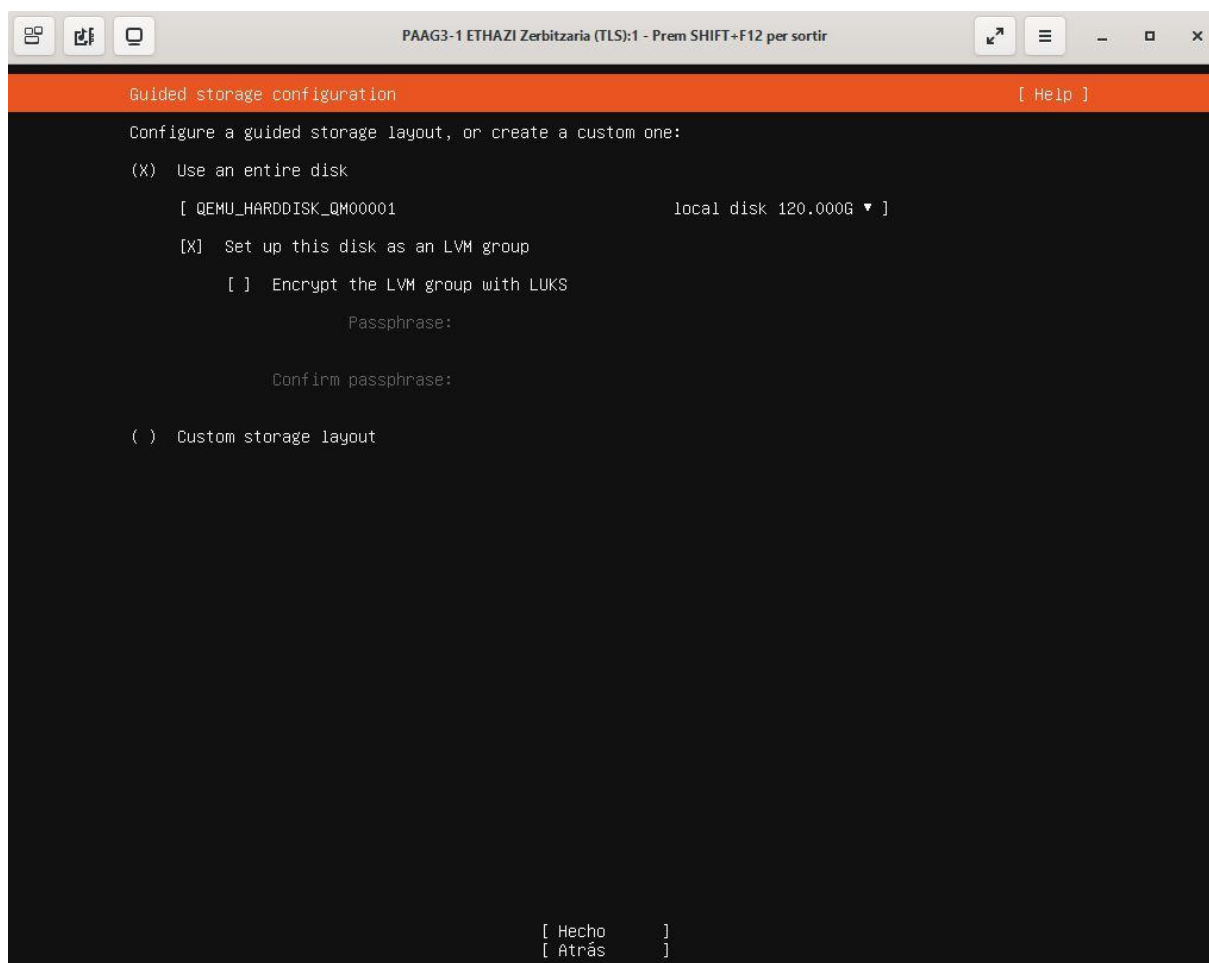

For the data of the account the installation manager will ask to enter some parameter like the name, name of the server etc. This is the account data we have entered.

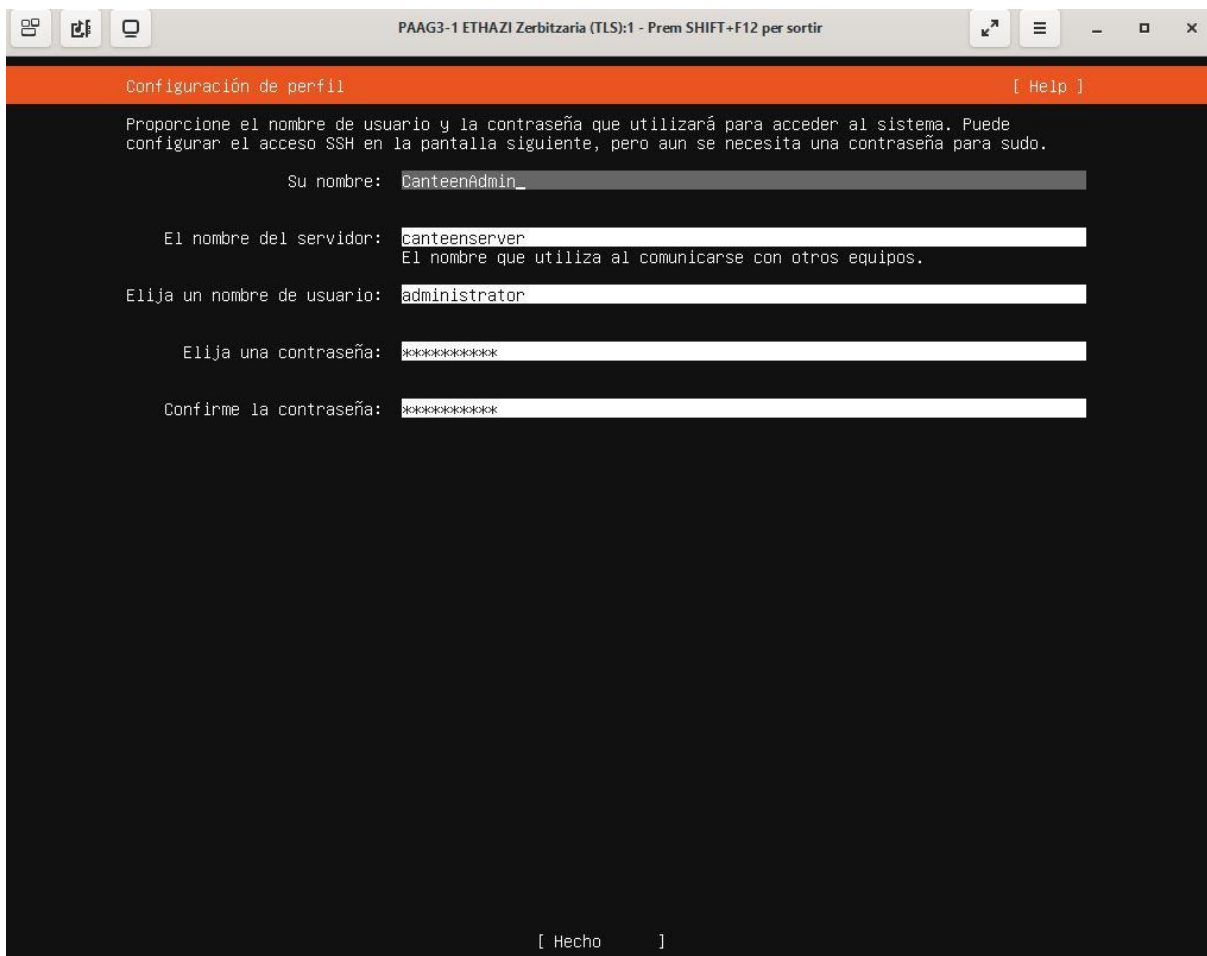

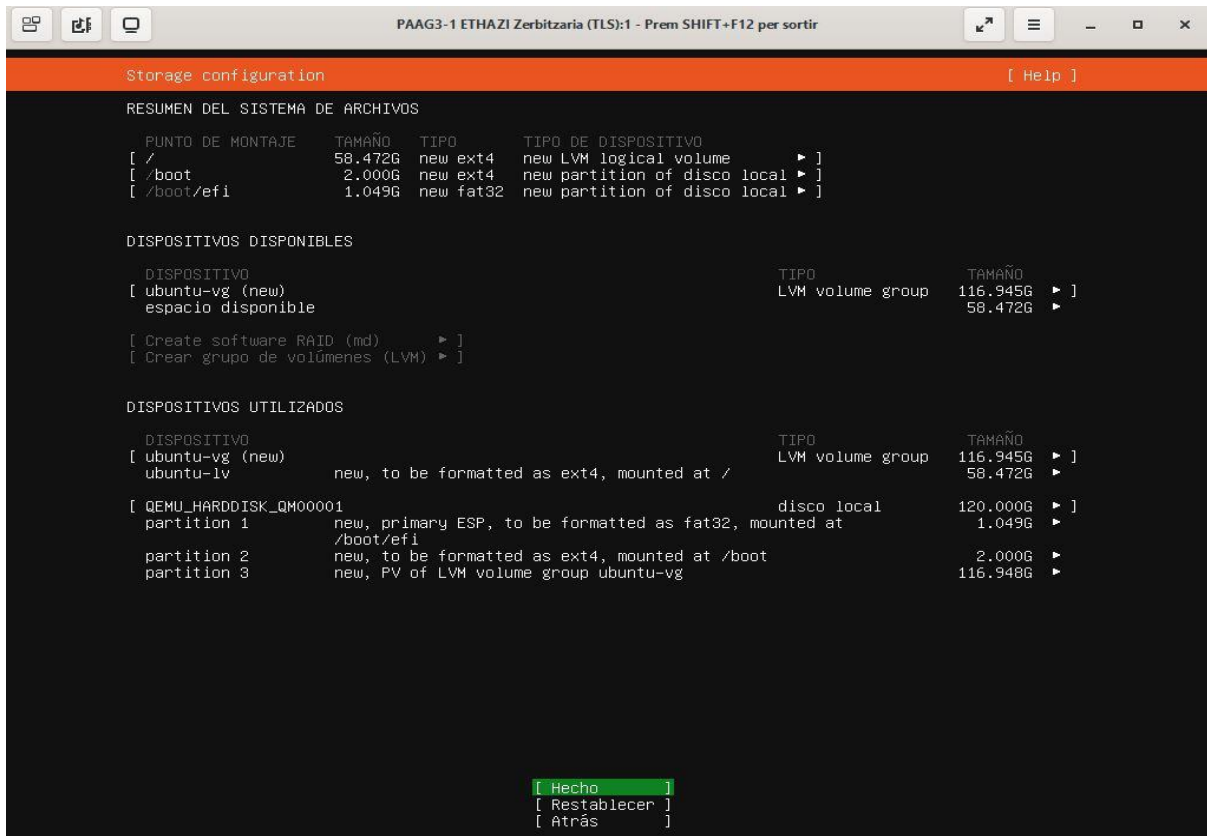

**Your name** => CanteenAdmin

**Name of the server** => canteenserver

**Username** => administrator

**Password** => UniCanteen

The last steps are the installation of the extensions and the configuration of the network structure. In our case we have only installed ssh to connect remotely from our computers, however the installation manager gives the option to install so many other options. Finally the last step will be the configuration of the network. In this step there are so many parameters to set like subnet, address, gateway etc. This are the parameters we have set:

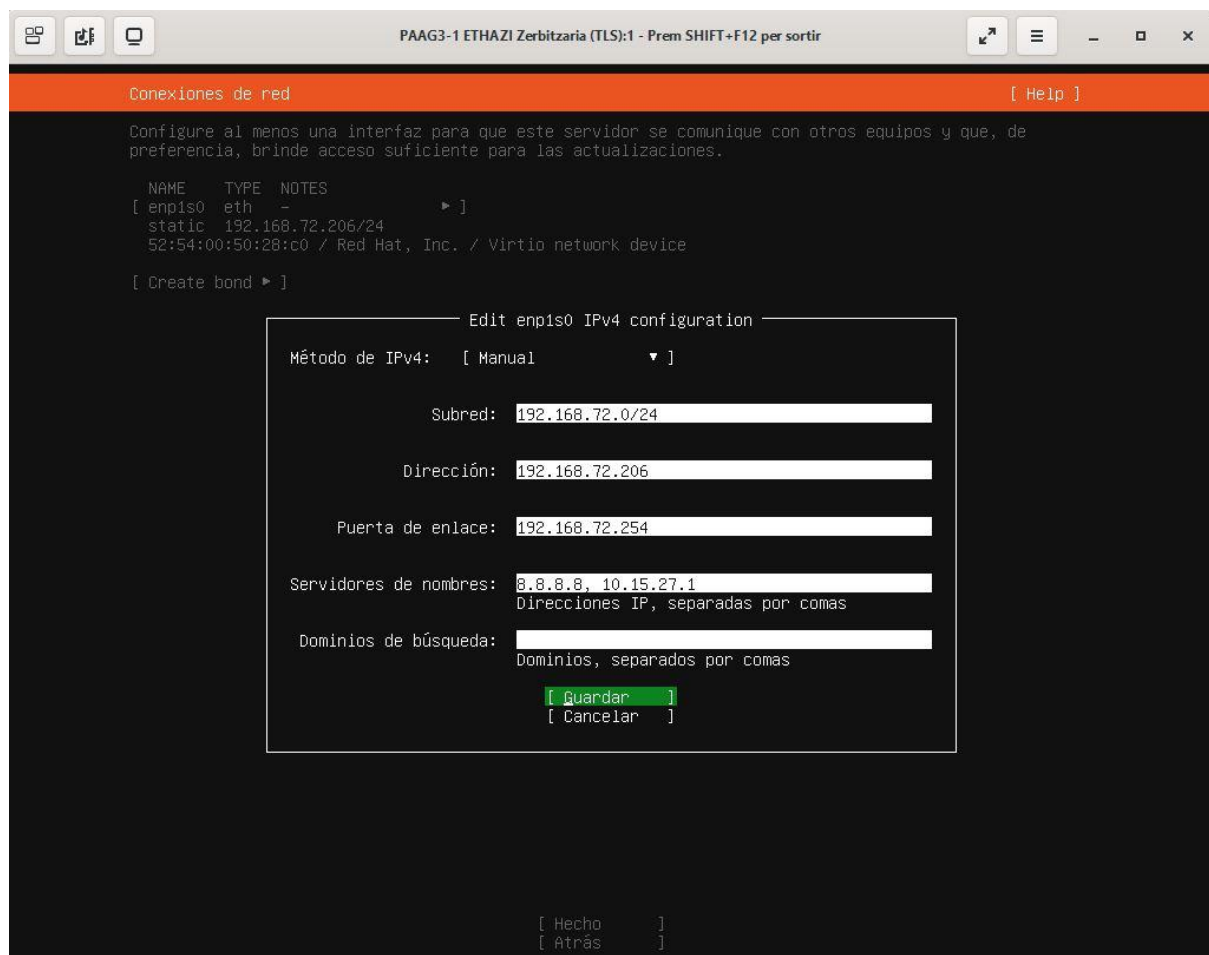

**Subnet** => 192.168.72.0/24

**Address** => 192.168.72.206

**Gateway** => 192.168.72.254

**Names server** => 8.8.8.8, 10.15.27.1

**Names domain** =>

## 2. WEBMIN

Once the installation is made we started configuring the server according to the needs of the project. Using ssh we are going to be able to connect remotely from our computers and we are going to be able to execute commands in an easier way. That's an essential part to install certain software in the server, the clearest example will be Webmin.

Webmin is a modern web control panel that allows you to manage your Linux server through a browser-based interface. With Webmin, you can manage user accounts, configure DNS settings, and change settings for common packages on the fly.

There are different ways to install Webmin, the way we have used is installing it by commands. First using ssh from our terminal we have connected to our server and then we have enter this commands one by one:

```
sudo sh -c 'echo "deb http://ftp.au.debian.org/debian/ buster main non-free" > /etc/apt/sources.list.d/nonfree.list'
```

```
sudo apt update
```

```
sudo apt install wget
```

```
wget -qO - http://www.webmin.com/jcameron-key.asc | sudo apt-key add -
```

```
sudo sh -c 'echo "deb http://download.webmin.com/download/repository sarge contrib" > /etc/apt/sources.list.d/webmin.list'
```

```
sudo apt update
```

```
sudo apt install webmin
```

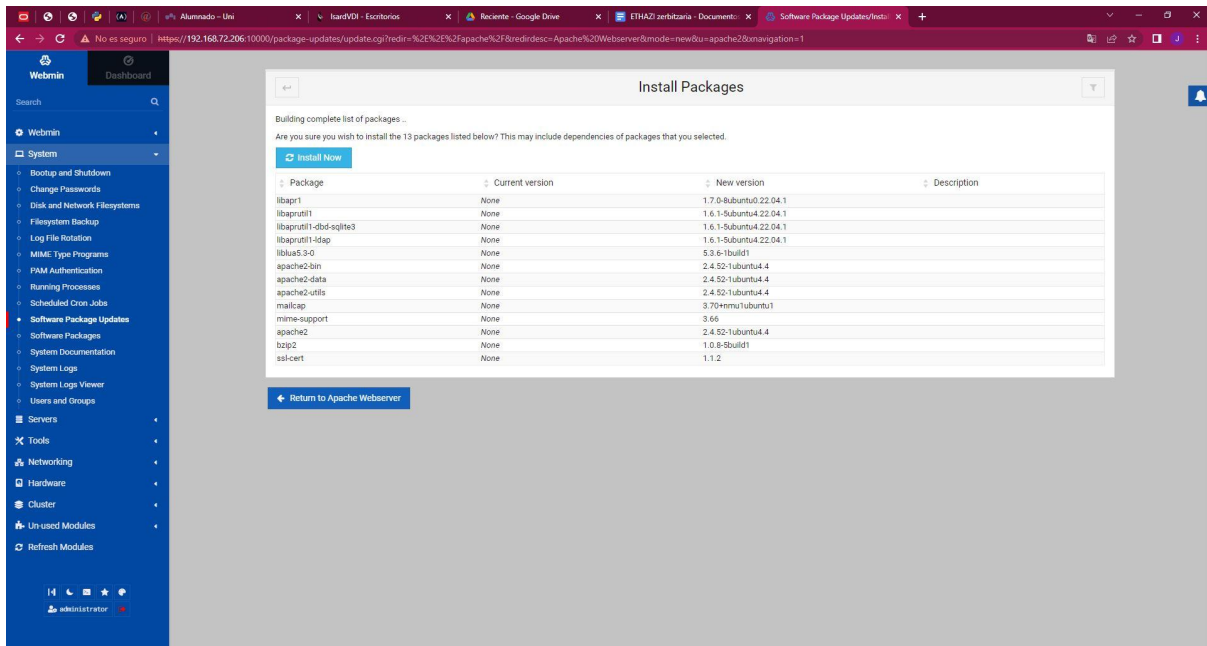

Once we have installed Webmin, we are going to enter the tool and we are going to keep configuring our server. The next step will be to make a web server using Apache and to make a DNS server.

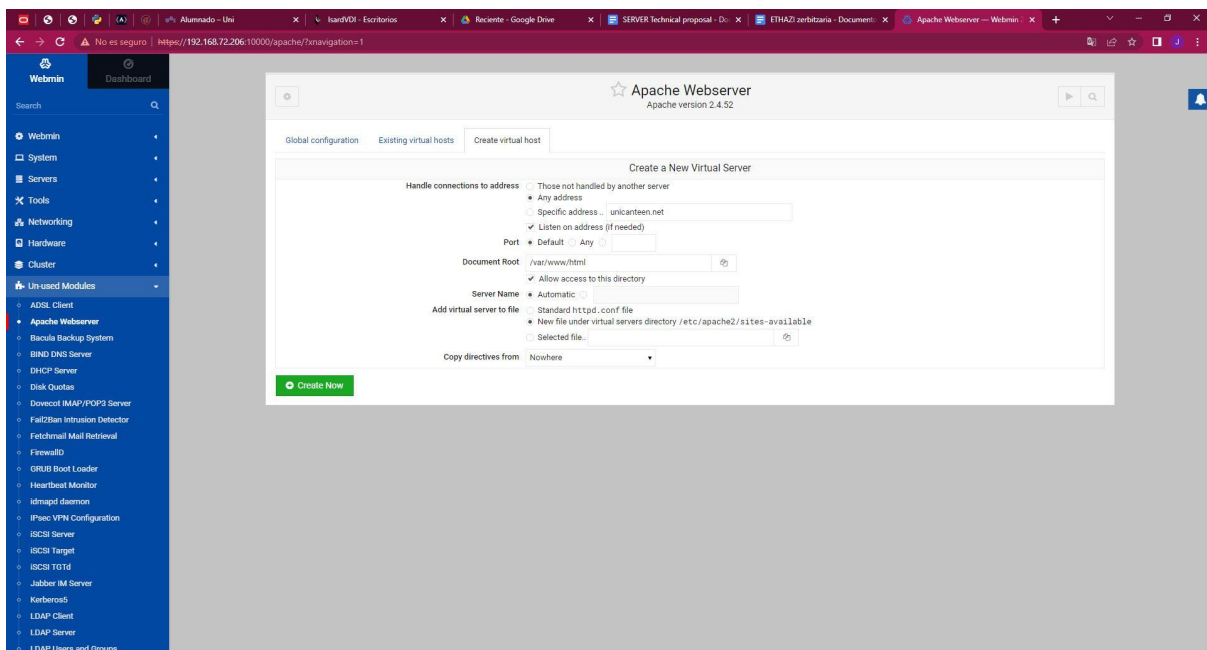

### 3. WEB AND DNS SERVER

A web server or HTTP server is a computer program that processes a server-side application, making two-way or one-way, synchronous or asynchronous connections to the client, and generating or returning a response in any language or client-side application.

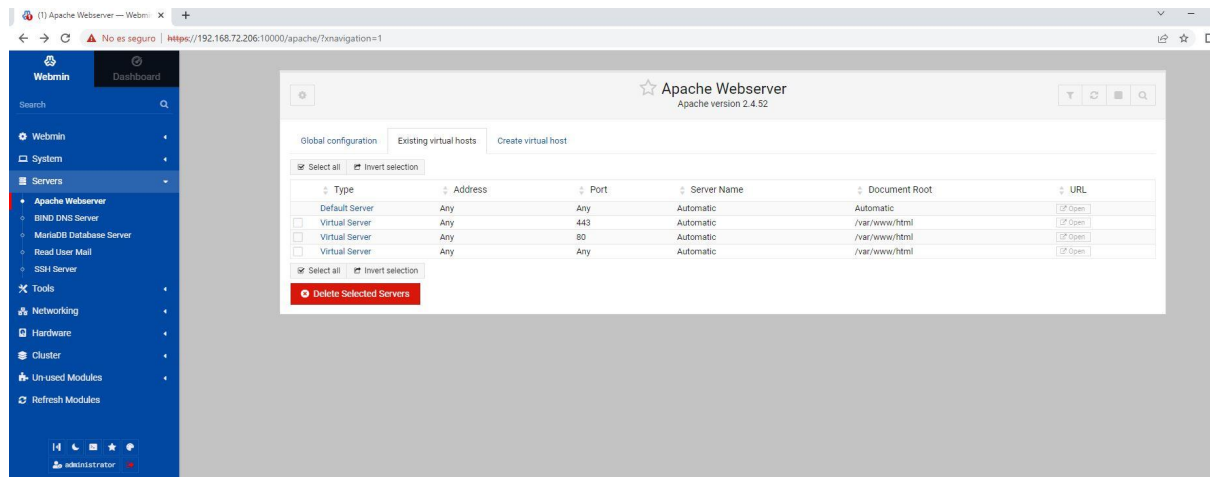

First of all we need to install the Apache web server module in our server, for that we will enter in servers and we will select Apache web server. Then we will install the module.

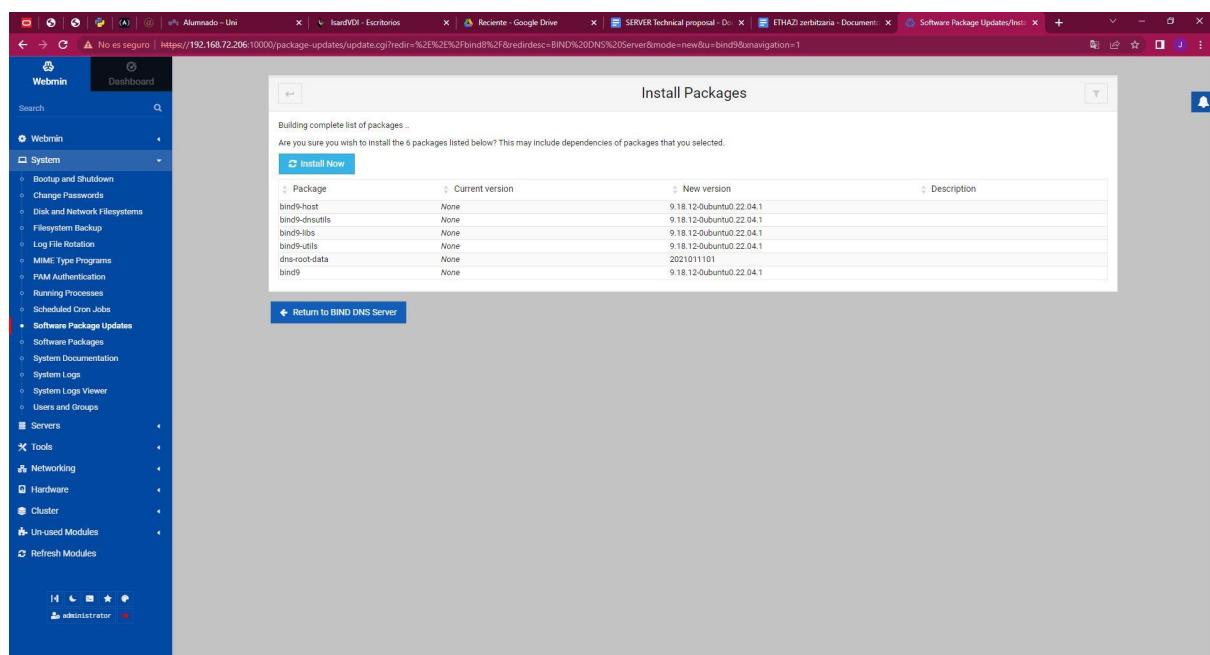

We will need to create a virtual host, in our case we have called **unicanteen.net** that will have the same address that our server has.

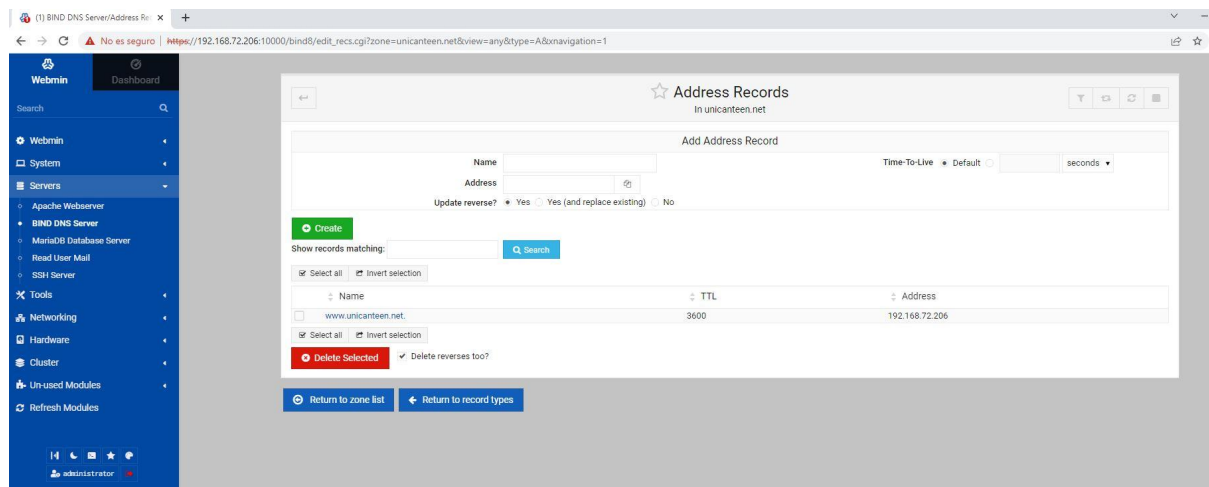

Once we have configured it, we'll get this. Our web site's HTML documents will be hosted in the `/var/www/html` directory.

After this we will install the DNS server. Will do the same procedure that we have done with the web server. First we will install the DNS server module.

Once we have installed we will configure the address for our virtual host.

## 4. PHP

Once we have configured our web server and DNS server we need to install PHP for our web site. PHP is a programming language designed to develop web applications and create web pages, favoring the connection between servers and the user interface. These are the two reason for why the language became so popular:

1. It is open source, there are no usage restrictions linked to rights. Users can use PHP to program in any project and market it without any problem.
2. Is constantly being refined, thanks to a proactive and engaged community of developers.

PHP is generally defined as a server-side language. This means that it is applied to the programming that takes place on the web server responsible for running the application or, more often, on a website.

This previous work allows the elements of a page to be loaded before showing them to the user who accesses a website, for example.

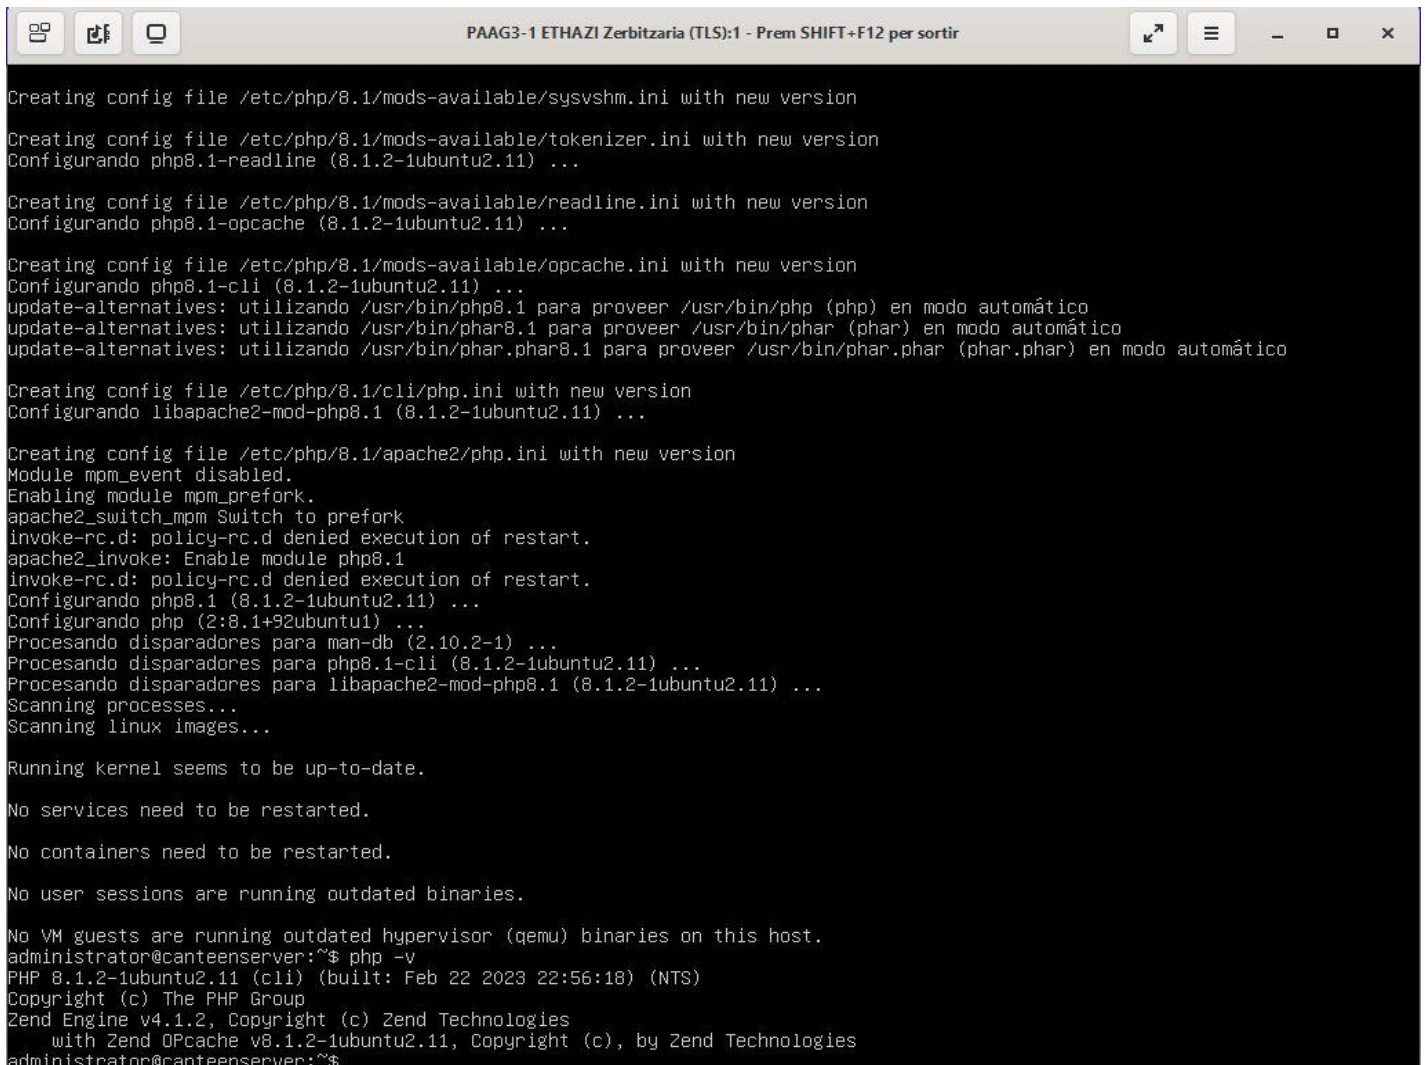

The PHP code is executed on the server which, by reading the commands, can activate all the functional elements and the visual interface of the website.

To ensure this service on our server we must enable PHP. To enable that we have entered these commands. Executing these commands we will get installed the latest version of php; 8.1.

**sudo apt-get update**

**sudo apt-get upgrade**

**sudo apt-get install php**

```

## **5. MARIADB**

Once we have enabled PHP it's time to install a database management system. For our information system we have chosen MariaDB.

MariaDB is a free and open source relational database management system (RDBMS). It was created by the original developers of MySQL.

The reason for the choice of MariaDB is that it offers the same features as MySQL and can be used as a direct replacement for the MySQL database server (ie MySQL can be uninstalled and MariaDB installed without any other changes). Designed for speed, reliability, and ease of use, MariaDB can be used for both small and enterprise-level processing tasks.

To install MariaDB on our server we have entered these commands. In our case we have installed the server version, so the commands will be a little bit different.

**sudo apt update**

**sudo apt install -y mariadb-server**

Once the installation is completed we use this command to check the status of MariaDB.

**systemctl status mariadb**

```
PAAG3-1 ETHAZI Zerbitzaria (TLS):1 - Prem SHIFT+F12 per sortir
administrator@canteenserver:~$ systemctl status mariadb

## 6. SECURITY MEASURES

### HTTPS PROTOCOL OR SSL CERTIFICATE

SSL (Secure Sockets Layer) is a standard protocol created for the secure transmission of information between a client and a server. It is usually used to secure communication between a web server and a browser, or between a mail server and a client.

SSL is specifically a security protocol. Protocols describe how algorithms should be used. In this case, SSL protocols define how to encrypt the data when we need to bind and send it. All browsers have the ability to interact with secure web servers using the SSL protocol.

However, both the browser and the server will need an SSL Certificate to establish a secure connection. SSL secures the data of millions of Internet users every day, especially during online transactions and the transmission of confidential information.

To install SSL in our server first we will enter this command:

```
sudo mkdir/etc/apache2/ssl
```

The next step will be entering this command line, then in the terminal will appear this text asking us to enter information for our SSL certificate:

[illegible]

```
You are about to be asked to enter information that will be incorporated
into your certificate request.
What you are about to enter is what is called a Distinguished Name or a DN.
There are quite a few fields but you can leave some blank
For some fields there will be a default value,
If you enter '.', the field will be left blank.
-----
Country Name (2 letter code) [AU]:SP
State or Province Name (full name) [Some-State]:Gipuzkoa
Locality Name (eg, city) []:Eibar
Organization Name (eg, company) [Internet Widgits Pty Ltd]:Uni Eibar
Organizational Unit Name (eg, section) []:Uni Canteen
Common Name (e.g. server FQDN or YOUR name) []:canteenserver
Email Address []:kaixo@uni.eus
root@canteenserver:/home/administrator#
```

After this we restart the apache service using this command:

```
systemctl restart apache2
```

After this we install the SSL module using this command:

```
sudo a2enmod ssl
```

After this we will set a default configuration for SSL:

```
sudo ln -s /etc/apache2/sites-available/default-ssl.conf
/etc/apache2/sites-enabled/000-default-ssl.conf
```

Now we will edit the default configuration of SSL:

```
sudo nano /etc/apache2/sites-enabled/000-default-ssl.conf
```

We will add this two lines to the SSL configuration:

```
SSLCertificateFile /etc/apache2/ssl/server.crt
SSLCertificateKeyFile /etc/apache2/ssl/server.key
```

Once everything is set we will restart Apache2 service and we will access our website to have a look at the certificate.

## BACKUP

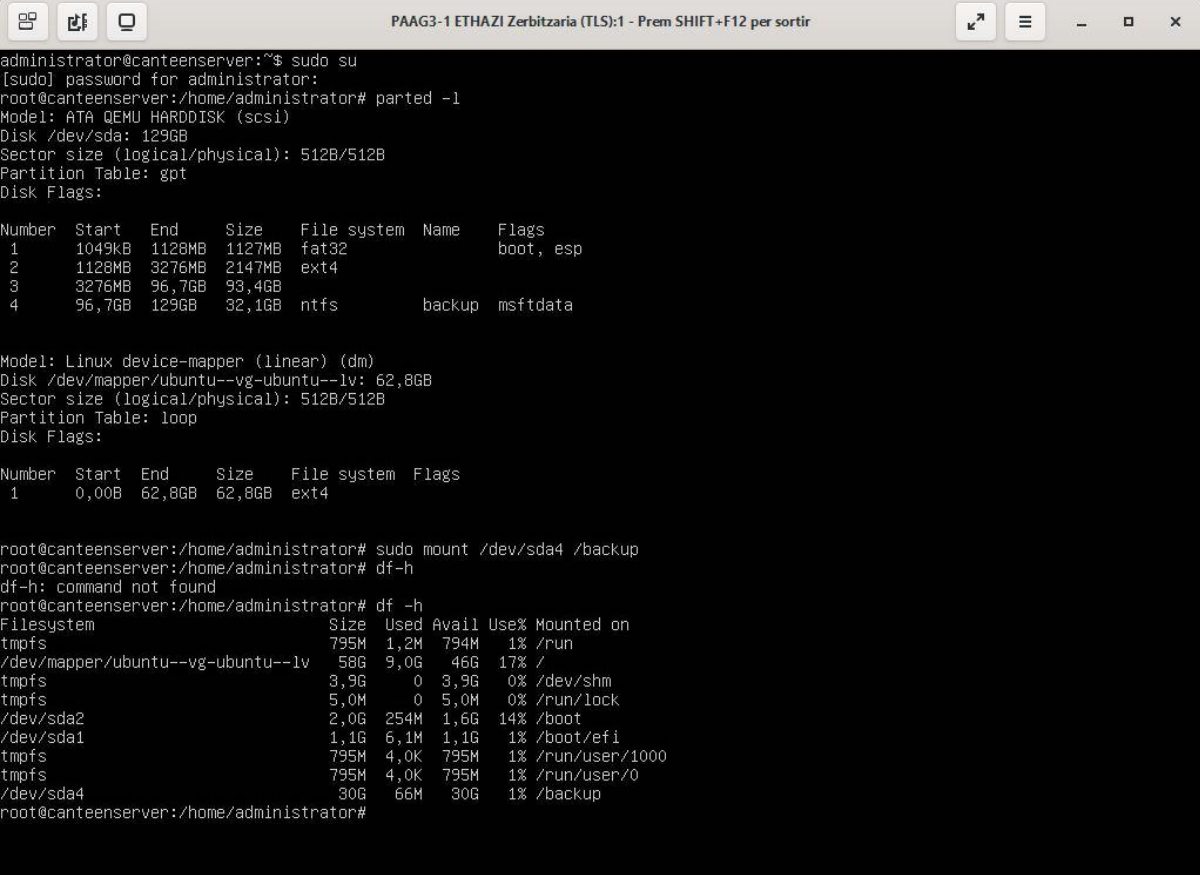

For creating a backup we need to create a partition of our disk. To do that we have modified our virtual machine and we have entered using an image to have access to the disk partitions. After doing that we have selected our main disk and we have free up space to create a new partition with that. We have freed up 30gb and we have mounted the partition; this partition is called backup.

After mounting the backup partition we are going to program and configure our backup. The backup has been done using webmin. Inside webmin we are going to enter **filesystem backup** and we are going to configure our backup.

First we are going to enter the directory where the backup is going to be stored. In our case will be in the backup directory that refers to the mounted backup partition.

A terminal window titled "PAAG3-1 ETHAZI Zerbitzaria (TLS):1 - Prem SHIFT+F12 per sortir" showing a series of commands and their outputs. The user starts as 'administrator@canteenserver' and runs 'sudo su' to become root. Then 'parted -l' is run to list disk partitions. The output shows a disk with four partitions: 1 (fat32, boot/esp), 2 (ext4), 3 (ntfs), and 4 (ntfs, backup). The user then runs 'df -h' to show disk usage, and 'df -h' is run again to show the updated usage after mounting partition 4 to /backup.

```
administrator@canteenserver:~$ sudo su
[sudo] password for administrator:
root@canteenserver:/home/administrator# parted -l
Model: ATA QEMU HARDDISK (scsi)
Disk /dev/sda: 129GB
Sector size (logical/physical): 512B/512B
Partition Table: gpt
Disk Flags:

Number  Start   End     Size    File system  Name      Flags
 1      1049KB  1128MB  1127MB  fat32         boot, esp
 2      1128MB  3276MB  2147MB  ext4
 3      3276MB  96,7GB  93,4GB  ntfs
 4      96,7GB  129GB   32,1GB  ntfs          backup  msftdata

Model: Linux device-mapper (linear) (dm)
Disk /dev/mapper/ubuntu--vg-ubuntu--lv: 62,8GB
Sector size (logical/physical): 512B/512B
Partition Table: loop
Disk Flags:

Number  Start   End     Size    File system  Flags
 1       0,00B  62,8GB  62,8GB  ext4

root@canteenserver:/home/administrator# sudo mount /dev/sda4 /backup
root@canteenserver:/home/administrator# df -h
df-h: command not found
root@canteenserver:/home/administrator# df -h
Filesystem      Size  Used Avail Use% Mounted on
tmpfs           795M  1,2M  794M   1% /run
/dev/mapper/ubuntu--vg-ubuntu--lv 58G   9,0G   46G  17% /
tmpfs           3,9G   0   3,9G   0% /dev/shm
tmpfs           5,0M   0   5,0M   0% /run/lock
/dev/sda2       2,0G  254M   1,6G  14% /boot
/dev/sda1       1,1G   6,1M   1,1G   1% /boot/efi
tmpfs           795M   4,0K  795M   1% /run/user/1000
tmpfs           795M   4,0K  795M   1% /run/user/0
/dev/sda4       30G   66M   30G   1% /backup
root@canteenserver:/home/administrator#
```

Then we are going to assign the backup to the directory that has the same name and we are going to create a file that is called “copy” to store the backup. This will be in TAR format and we have also selected to compress in gzip format. Finally we schedule the backup and then we click to create.
